The three-dimensional nature of plasmoid instabilities is studied using the reduced magnetohydrodynamic equations. For a Harris equilibrium with guide field, represented by $\mathbf{B}_o = B_{po} \tanh(x/\lambda)\hat{y} + B_{zo}\hat{z}$, a spectrum of modes are unstable at multiple resonant surfaces in the current sheet, rather than just the null surface of the poloidal field $B_{yo}(x) = B_{po} \tanh(x/\lambda)$, which is the only resonant surface in 2D or in the absence of a guide field. Here, B_{po} is the asymptotic value of the equilibrium poloidal field, B_{zo} is the constant equilibrium guide field, and λ is the current sheet width. Plasmoids on each resonant surface have a unique angle of obliquity $\theta \equiv \arctan(k_z/k_y)$. The resonant surface location for angle θ is $x_s = \lambda \operatorname{arctanh}(\mu)$, where $\mu = \tan\theta B_{zo}/B_{po}$ and the existence of a resonant surface requires $|\theta| < \arctan(B_{po}/B_{zo})$. The most unstable angle is oblique, i.e., $\theta \neq 0$ and $x_s \neq 0$, in the constant- ψ regime, but parallel, i.e., $\theta = 0$ and $x_s = 0$, in the nonconstant- ψ regime. For a fixed angle of obliquity, the most unstable wavenumber lies at the intersection of the constant- ψ and nonconstant- ψ regimes. The growth rate of this mode is $\gamma_{\max}/\Gamma_o \simeq S_L^{1/4}(1 - \mu^4)^{1/2}$, in which $\Gamma_o = V_A/L$, V_A is the Alfvén speed, L is the current sheet length, and S_L is the Lundquist number. The number of plasmoids scales as $N \sim S_L^{3/8}(1 - \mu^2)^{-1/4}(1 + \mu^2)^{3/4}$. © 2012 American Institute of Physics. [doi:10.1063/1.3678211]

I. INTRODUCTION

Plasmoid dominated reconnection occurs when a thin current sheet breaks into a chain of secondary islands, or plasmoids, which convect along the reconnection outflow, eventually removing magnetic field from the current sheet.^{1–13} Before being ejected, plasmoids may coalesce,¹⁴ and current sheets between plasmoids can excite new generations of plasmoids.^{10,13} This process may be considered turbulent if it can repeat sufficiently many times.^{15,16} Since plasmoid dominated reconnection proceeds much faster than the conventional Sweet-Parker^{17,18} rate, onset of the instability can trigger fast reconnection. In 3D, plasmoids are tube-like in shape, see Fig. 1, and are often called flux ropes. There is significant observational evidence for flux ropes in astrophysical reconnection sites including solar flares,¹⁹ and the Earth's magnetopause²⁰ and magnetotail.²¹ Similar tearing instabilities are also important in magnetic confinement fusion experiments.

Magnetohydrodynamic (MHD) theories of tearing instabilities are typically 2D in that they take the guide field direction (\hat{z}) to be ignorable.^{22,23} For these parallel modes, $k_z = 0$, flux ropes are aligned with the guide field as shown in Fig. 1(a). Oblique tearing modes, with $k_z \neq 0$, are a 3D effect. In tokamak parlance, oblique modes are those with $n \neq 0$, where n is the toroidal mode number. The primary differences between tokamak tearing modes²⁴ and plasmoid instabilities^{1,2} are the current distributions and boundary conditions. Tearing modes are instabilities of diffuse current distributions, whereas plasmoids are secondary instabilities of thin current sheets. The difference has consequences for how the instabilities scale with resistivity. Boundaries are periodic in both the toroidal and poloidal directions in a tokamak, whereas in astrophysical situations in which current sheets arise boundaries are often open or line-tied.

It has recently been shown² that the linear plasmoid instability¹ can be related to the conventional tearing mode²² in a simple way. For a Harris equilibrium²⁵ without guide field, $\mathbf{B}_o = B_{po} \tanh(x/\lambda)\hat{y}$, the classical tearing mode growth rate is²³

$$\gamma\tau_A \sim \begin{cases} S^{-3/5}(k\lambda)^{-2/5}(1 - k^2\lambda^2)^{4/5}, & k\lambda S^{1/4} \gg 1, \\ S^{-1/3}(k\lambda)^{2/3}, & k\lambda S^{1/4} \ll 1, \end{cases} \quad (1)$$

for the constant- ψ and nonconstant- ψ regimes, respectively. The maximum growth rate occurs at the intersection of the two branches, $k\lambda S^{1/4} \simeq 1$, where $\gamma_{\max}\tau_A \sim S^{-1/2}$. Here, $S = \tau_R/\tau_A$ is the Lundquist number based on the current sheet width, $\tau_R = 4\pi\lambda^2/(\eta c^2)$ is the resistive diffusion time, $\tau_A = \lambda/V_A = \lambda\sqrt{4\pi\rho}/B_{po}$ is the Alfvén time, and k is the wavenumber. The recent insight connecting the plasmoid growth rate¹ with Eq. (1) was to account for the Lundquist number scaling of the current sheet width.² MHD current sheets obey the Sweet-Parker width $\lambda = \delta_{\text{SP}} = LS_L^{-1/2}$, in which $S_L = 4\pi LV_A/(c^2\eta) = (L/\lambda)S$ is the Lundquist number based on the current sheet length. For a current sheet, the maximum growth rate from Eq. (1) is $\gamma_{\max} \simeq S_L^{1/4}V_A/L$, which scales with S_L to a positive exponent, rather than the negative exponent scaling of the most unstable tearing mode. Because current sheets becomes increasingly singular at high S_L , the plasmoid growth rate is large for high S_L plasmas such as the solar corona ($S_L \gtrsim 10^{12}$) and fusion experiments ($S_L \gtrsim 10^6$). Plasmoid growth rates that scale with S_L to a positive exponent have also been calculated in the Hall MHD regime.¹²

The present work is motivated by a recent study by Daughton *et al.*¹⁵ who showed using linear Vlasov and particle-in-cell simulations of the Harris current sheet²⁵ that

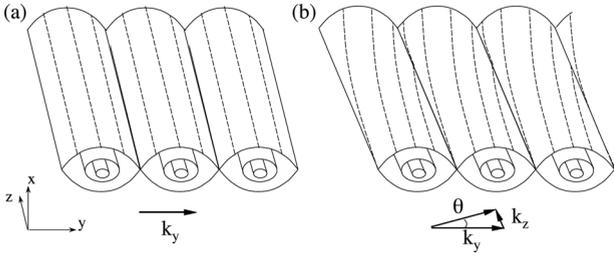

FIG. 1. Schematic depiction of constant flux surfaces of plasmoids in 3D. Dashed lines designate the guide field direction (\hat{z}). Flux ropes for parallel modes (a) are aligned with the guide field, while for oblique modes (b) they are misaligned by angle θ .

the conventional collisionless kinetic theory²⁶ breaks down for oblique modes. They suggest that this is a failure of asymptotic boundary layer analysis, which is a challenge to analytic theory. Here, we consider the simpler resistive MHD problem and show that, at least within this framework, boundary layer theory can faithfully describe oblique tearing modes. This regime is important in its own right since many reconnection problems of interest are sufficiently collisional that a resistive MHD model is warranted. The spectrum of oblique tearing modes has important consequences for the generation of turbulence by overlapping flux ropes.¹⁵ It is also important when considering whether plasmoids can fill the volume of a current sheet, which is an important assumption in some particle acceleration theories.²⁷ We find that plasmoids are volume filling, but the angle of obliquity and growth rate depend on the resonant surface location. A numerical study of oblique tearing using Hall MHD without guide field has been presented by Cao and Kan.²⁸ Huang and Zweibel²⁹ studied the reduced MHD problem numerically, with guide field, focusing on line-tied boundary conditions.

Plasmoid instabilities arise at resonant surfaces of the ideal MHD equations, defined by $\mathbf{k} \cdot \mathbf{B}_o = 0$, near which dissipation (resistivity here) allows for reconnection of magnetic field.²² The primary difference between the 2D and 3D theories is the location of resonant surfaces. For a Harris sheet with guide field, $\mathbf{B}_o = B_{po} \tanh(x/\lambda) \hat{y} + B_{zo} \hat{z}$, resonant surfaces are located at $x_s = -\lambda \arctan(\tan \theta B_{zo}/B_{po})$, where $\theta = \arctan(k_z/k_y)$ is the angle of obliquity. In the conventional 2D theories, either $B_{zo} = 0$ or $k_z = 0$, in which case there is a single resonant surface corresponding to the null of the sheared field $x_s = 0$. In the 3D problem, resonant surfaces can be found at any location across the current sheet. Modes at each surface correspond to different angles of obliquity. The angle for a mode at surface location x is $\theta = \arctan[\tanh(-x/\lambda) B_{po}/B_{zo}]$. Parallel modes ($\theta = 0$) are found at the null surface of the poloidal field, and the magnitude of the angle of the mode increases with distance from the null surface. The existence of a resonant surface requires $|\theta| < \arctan(B_{po}/B_{zo})$. We show that for large k (the constant- ψ regime), the most unstable mode is oblique, satisfying $\theta \simeq \pm (B_{po}/B_{zo}) \sqrt{(1 + k^2 \lambda^2)}/3$, and that parallel modes are a local minimum of the growth rate. For small k (the non-constant- ψ regime), parallel modes are the most unstable, and the growth rate falls off monotonically with $|\theta|$.

The rest of this paper is organized as follows. Section II describes the reduced MHD equations that form the basis of this analysis. Section III provides a boundary layer theory for the tearing mode growth rate, and this is used to derive the dispersion relation for the plasmoid instability. These results are compared with direct numerical solutions of the linearized reduced MHD equations in Sec. IV. Section V discusses numerical solutions of the flux and stream functions, which change with the angle of the mode. Section VI provides a summary of the results.

II. REDUCED MHD EQUATIONS

The reduced MHD equations are based on tokamak ordering,³⁰

$$\begin{aligned} \partial_x, \partial_y, B_{zo} &\sim \mathcal{O}(1), \\ \partial_z, \partial_t, \psi_o, \phi_o, V_{zo} &\sim \mathcal{O}(\epsilon), \\ B_{z1}, V_{z1}, \psi_1, \phi_1 &\sim \mathcal{O}(\epsilon^2), \end{aligned} \quad (2)$$

assuming a constant plasma density, a strong, constant, guide field (in the \hat{z} direction here), and that wavelengths in the guide field direction are much longer than in the perpendicular directions.

Applying these approximations, the MHD equation of motion,

$$(\partial_t + \mathbf{V} \cdot \nabla) \mathbf{V} = \mathbf{J} \times \mathbf{B} - \nabla P, \quad (3)$$

Ohm's law,

$$\mathbf{E} + \mathbf{V} \times \mathbf{B} = S^{-1} \mathbf{J}, \quad (4)$$

and the relevant Maxwell equations, $\nabla \cdot \mathbf{B} = 0$, $\nabla \times \mathbf{E} = -\partial_t \mathbf{B}$, and $\nabla \times \mathbf{B} = \mathbf{J}$, lead to the reduced MHD equations,³⁰

$$\partial_t \Omega + [\Omega, \phi] = [J_z, \psi] + B_z \partial_z J_z, \quad (5)$$

$$\partial_t \psi = B_z \partial_z \phi + [\phi, \psi] + S^{-1} \nabla_{\perp}^2 \psi + E_o. \quad (6)$$

Here, the stream function is defined by $\mathbf{V} = \nabla_{\perp} \phi \times \hat{z} + V_z \hat{z}$, the flux function by $\mathbf{B} = \nabla_{\perp} \psi \times \hat{z} + B_z \hat{z}$, $\Omega \equiv -\nabla_{\perp}^2 \phi$ is the vorticity, $J_z = -\nabla_{\perp}^2 \psi$ is the electric current in the \hat{z} direction, E_o and V_o are constants of integration, $\nabla_{\perp} = \partial_x \hat{x} + \partial_y \hat{y}$ is the perpendicular gradient, and $[f, g] = (\nabla f \times \nabla g) \cdot \hat{z}$ is the Poisson bracket. Spatial scales are normalized to the current sheet width ($\tilde{\mathbf{x}} = \mathbf{x}/\lambda$), velocities to the Alfvén speed ($\tilde{\mathbf{V}} = \mathbf{V}/V_A$), time to the Alfvén time $\tilde{t} = V_A t/\lambda$, magnetic field to the magnitude of the asymptotic poloidal magnetic field ($\tilde{\mathbf{B}} = \mathbf{B}/B_{po}$), and currents by $\tilde{\mathbf{J}} = \mathbf{J}/[cB_{po}/(4\pi\lambda)]$. Tildes have been omitted for notational convenience.

We linearize Eqs. (5) and (6) according to $f = f_o + \delta f$ in which $\psi_o = \psi_o(x)$, $\phi_o = \phi_o(x, y)$, and B_{zo} is constant. We also assume that flow profiles satisfy, $\nabla_{\perp}^2 \phi_o = 0$, and that the instability growth rate is much larger than the timescale for equilibrium flows, $\partial_x \phi_o, \partial_y \phi_o \ll \gamma$. Perturbations satisfy $\delta f = f_1(x) \exp[i(k_y y + k_z z) + \gamma t]$. Applying this procedure, and the tokamak ordering (2), the linearized form of Eqs. (5) and (6) are

$$\gamma(\phi_1'' - k_y^2 \phi_1) = iF(\psi_1'' - k_y^2 \psi_1) - iF''\psi_1, \quad (7)$$

$$\gamma\psi_1 = iF\phi_1 + S^{-1}(\psi_1'' - k_y^2 \psi_1), \quad (8)$$

in which $F \equiv \mathbf{k} \cdot \mathbf{B}_o$ and primes denote x derivatives. Tokamak ordering implies $k = |k_y|[1 + \mathcal{O}(\epsilon)]$ and $k_z/k_y = \tan(\theta) \simeq \theta + \mathcal{O}(\epsilon^3)$, where $\theta \sim \mathcal{O}(\epsilon)$. In the remainder of this work, we adopt the notation (k, θ) in place of (k_y, k_z) . Thus, $F = \mathbf{k} \cdot \mathbf{B}_o = k[B_{oy}(x) + \theta B_{oz}]$, which is an $\mathcal{O}(\epsilon)$ quantity.

III. BOUNDARY LAYER ANALYSIS

A. Outer region

In the outer region, we assume $S^{-1} \ll \gamma \ll 1$, in which case Eq. (7) reduces to the classical ideal MHD outer region of Furth, Killeen, and Rosenbluth (FKR),²²

$$\psi_1'' - (k^2 + F''/F)\psi_1 = 0. \quad (9)$$

Equation (9) holds everywhere except a small region about the resonant surfaces, where $F = 0$. We follow the conventional boundary layer analysis, which matches the jump in the first derivative of ψ_1 , denoted the tearing stability index,

$$\Delta' \equiv [\psi_1'(x_s^+) - \psi_1'(x_s^-)]/\psi_1(x_s), \quad (10)$$

in the inner and outer regions. Here, $x_s^\pm = \lim_{\epsilon \rightarrow 0}(x_s \pm \epsilon)$, and ψ_1 is continuous at x_s .

FKR provides an asymptotic analysis for Δ' in the large and small k limits. For $k^2 \gg \partial_x^2$, the solution of Eq. (9) is $\psi_1 = \psi_1(x_s) \exp(-k|x - x_s|)$, so $\Delta' \rightarrow -2k$ in this limit. For $k^2 \ll \partial_x^2$, FKR show $\Delta' \rightarrow (1/k)[F'(x_s)]^2(F_{-\infty}^{-2} + F_{\infty}^{-2})$. An approximate solution that captures both the large and small k limits can be obtained by adding the asymptotic solutions,

$$\Delta' \simeq (\alpha^2/k)(F_{-\infty}^{-2} + F_{\infty}^{-2}) - 2k, \quad (11)$$

in which $\alpha \equiv F'(x = x_s) = kB'_{oy}(x = x_s)$.

For the Harris equilibrium with a guide field, $\mathbf{B}_o = B_{po} \tanh(x)\hat{y} + B_{zo}\hat{z}$ and $x_s = -\lambda \arctanh(\mu)$ where $\mu \equiv k_z B_{zo}/(k_y B_{po}) \simeq \theta B_{zo}/B_{po}$. Thus, $\alpha = kB_{po}(1 - \mu^2)$, and Eq. (11) yields

$$\Delta'_H \simeq 2[(1 + \mu^2)/k - k]. \quad (12)$$

Figures 2 and 3 show that Eq. (12) agrees well with numerical solutions of Eq. (9) for the Harris equilibrium. Solutions are shown for $B_{po}/B_{zo} = 0.1$, at fixed wavenumbers varying the angle (Fig. 2) and at fixed angles varying the wavenumber (Fig. 3). Daughton *et al.*¹⁵ have also proposed the solution,

$$\Delta'_D \simeq 2\left(\frac{1}{k} - k\right) \left[1 + \mu^2 \frac{(1 - k/2)}{1 - k}\right], \quad (13)$$

for a Harris equilibrium with guide field. Predictions of Eq. (13) are also shown in Figs. 2 and 3.

For small k , Eqs. (12) and (13) both asymptote to $\Delta' \rightarrow 2(1 + \mu^2)/k$. However, for large k , $\Delta'_H \rightarrow -2k$, while $\Delta'_D \rightarrow -k(2 + \mu^2)$. The μ dependence of the large k limit of

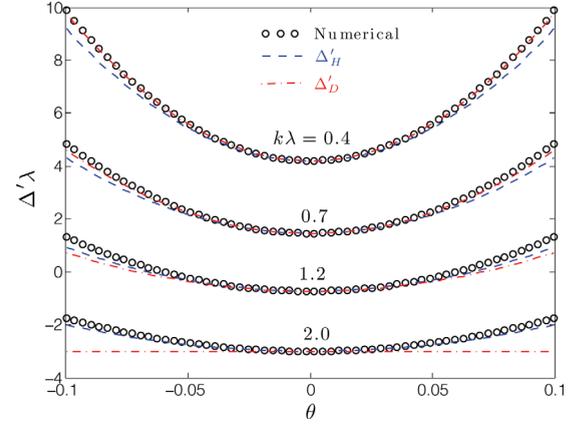

FIG. 2. (Color online) Angular dependence of the tearing stability index for a Harris equilibrium with $B_{po}/B_{zo} = 0.1$, and four different wavenumbers: $k\lambda = 0.4, 0.7, 1.2$, and 2.0 . Black circles show a numerical solution of Eq. (9), blue dashed lines the FKR approximation from Eq. (12), and red dash-dotted lines Daughton's approximation from Eq. (13).

Eq. (13) is incorrect, as the asymptotic solution of Eq. (9) and Fig. 3 show. However, Eq. (13) provides an excellent approximation for small k . This is typically the most interesting case since tearing instability requires $\Delta' > 0$ and Δ' becomes negative for large k . The simple expression (12) provides an adequate approximation for all k and θ , capturing both asymptotic limits. Both results are exact for normal modes ($\theta = 0$).²² Figure 2 shows that an interesting situation can arise for $k \sim 1$, where oblique modes are unstable, $\Delta'(\theta \neq 0) > 0$, but normal modes are stable, $\Delta'(\theta \simeq 0) < 0$. This feature is discussed in detail in Sec. IV. Figures 2 and 3 include only $|\theta| < 0.1$, since there is no resonant surface for $|\theta| \geq B_{po}/B_{zo} = 0.1$.

B. Inner region

In the inner region, $x - x_s \equiv \xi \ll 1$, we assume $\partial_x^2 = \partial_\xi^2 \gg k_y^2$ and expand F to linear order about the resonant surface: $F \simeq F'(x_s)(x - x_s) \equiv \alpha\xi$. Here, Eqs. (7) and (8) reduce to

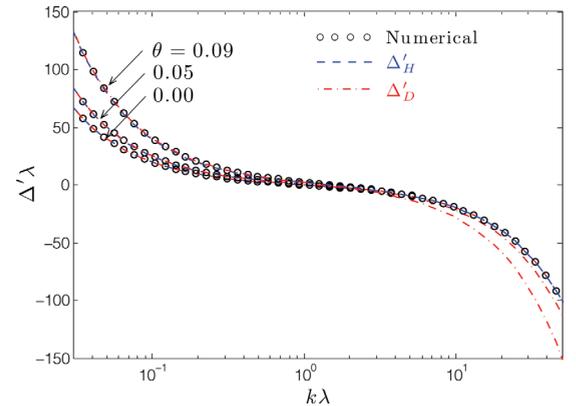

FIG. 3. (Color online) Wavenumber dependence of the tearing stability index for a Harris equilibrium with $B_{po}/B_{zo} = 0.1$, and three values of the angle of obliquity: $\theta = 0.00, 0.05$, and 0.09 radians. Black circles show a numerical solution of Eq. (9), blue dashed lines the FKR approximation from Eq. (12), and red dash-dotted lines Daughton's approximation from Eq. (13).

$$\gamma(i\phi_1)'' = -\alpha\xi(\psi_1)'' \quad (14)$$

and

$$\gamma\psi_1 - \alpha\xi(i\phi_1) = S^{-1}\psi_1''. \quad (15)$$

Equations (14) and (15) are the same equations used by Coppi *et al.*²³ to calculate Δ' in the inner layer. We provide an alternative derivation using a Fourier transform method similar to that developed by Bondeson *et al.*³¹ and Porcelli *et al.*^{32,33}

The fourth-order system of Eqs. (14) and (15) has solutions with ψ_1 constant, linear, and a solution where ψ_1 is an even function of ξ [$\psi_1(-\xi) = \psi_1(\xi)$]. We are interested in the last of these. For large ξ , Eqs. (14) and (15) reduce to

$$(\gamma/\alpha)^2(\psi_1/\xi)'' + \xi\psi_1'' = 0, \quad (16)$$

which has the solution $\psi_1 = a_1\xi + a_2\xi \arctan(\alpha\xi/\gamma)$. For large ξ , the asymptotic limit of this is

$$\psi_1 \rightarrow A|\xi| + B(1 - \frac{\gamma^2}{3\alpha^2} \frac{1}{\xi^2}) + \mathcal{O}(\xi^{-4}), \quad (17)$$

where A and B are constants. Equations (10) and (17) imply

$$\Delta' = 2A/B. \quad (18)$$

The coefficients A and B can be calculated by matching Eq. (17) with an exact solution of Eqs. (14) and (15). It is convenient to do this matching in a Fourier-transformed space: $\hat{f}(p) = \int_{-\infty}^{\infty} d\xi \exp(-ip\xi)f(\xi)$. Applying this, Eq. (17) can be written as

$$\hat{\psi}_1 \rightarrow -\frac{2A}{p^2} + B\left(2\pi\delta(p) + \frac{\pi\gamma^2}{3\alpha^2}|p|\right) + \mathcal{O}(p^3). \quad (19)$$

The fourth order system of Eqs. (14) and (15) can be written as a second order equation for $\hat{\psi}_1$,

$$\frac{d}{d\bar{p}} \left[\frac{1}{\bar{p}^2} \frac{d}{d\bar{p}} (\bar{p}^2 \hat{\psi}_1) \right] = \Lambda(\Lambda + \bar{p}^2) \hat{\psi}_1, \quad (20)$$

in which $\Lambda \equiv \gamma S^{1/3} \alpha^{-2/3}$ and $\bar{p} \equiv (S\alpha)^{-1/3} p$. The solution of Eq. (20) is

$$\hat{\psi}_1 = \frac{C_1}{\bar{p}^{3/2}} M_{\nu,3/4}(\sqrt{\Lambda}\bar{p}^2) + \frac{C_2}{\bar{p}^{3/2}} W_{\nu,3/4}(\sqrt{\Lambda}\bar{p}^2), \quad (21)$$

in which M and W are the Whittaker-M and W functions, $\nu \equiv -\Lambda^{3/2}/4$, and C_1 and C_2 are constants.

The first term of Eq. (21) diverges for large \bar{p} , so we must take $C_1 = 0$. For $\bar{p} \ll 1$,

$$W_{\nu,3/4}/\bar{p}^{3/2} = a(\bar{p}^{-2} + \Lambda^{7/4}/2) + b|\bar{p}| + \mathcal{O}(\bar{p}^2), \quad (22)$$

in which $a \equiv \sqrt{\pi}/\{2\Lambda^{1/8}\Gamma[(\Lambda^{3/2} + 5)/4]\}$ and $b = 4\sqrt{\pi}\Lambda^{5/8}/\{3\Gamma[(\Lambda^{3/2} - 1)/4]\}$. Matching the coefficients of Eqs. (19) and (21) gives $A = -C_2(S\alpha)^{2/3}a/2$ and $B = 3C_2(S\alpha)^{1/3}b/(\pi\Lambda^2)$. With these, Eq. (18) provides the dispersion relation

$$\Delta' = -\frac{\pi}{8}(S\alpha)^{1/3}\Lambda^{5/4} \frac{\Gamma[(\Lambda^{3/2} - 1)/4]}{\Gamma[(\Lambda^{3/2} + 5)/4]}. \quad (23)$$

Equation (23) was first obtained by Coppi *et al.*²³

Analytically tractable solutions for the growth rate can be obtained from Eq. (23) in the limits $\Lambda \ll 1$ (the constant- ψ regime),

$$\gamma = \left[\frac{\Gamma(1/4)}{2\pi\Gamma(3/4)} \right]^{4/5} S^{-3/5} \alpha^{2/5} \Lambda^{4/5}, \quad (24)$$

and $\Lambda \rightarrow 1^-$ (the nonconstant- ψ regime),

$$\gamma = \alpha^{2/3} S^{-1/3} - \frac{2\sqrt{\pi}\alpha}{3\Delta'}. \quad (25)$$

The second term in Eq. (25) causes stabilization at large k , but is typically negligible for the most unstable mode.

IV. LINEAR GROWTH RATE

The dispersion relation for the linear tearing mode growth rate is obtained by equating Eqs. (12) and (23). These equations can also be used to derive the plasmoid dispersion relation for a Sweet-Parker current sheet, as was done for parallel modes in Ref. 2 using the method summarized in Sec. I. In terms of unnormalized units, the tearing mode growth rate in the constant- ψ and nonconstant- ψ regimes from Eqs. (24) and (25) are

$$\gamma\tau_A \sim \begin{cases} S^{-3/5}(k\lambda)^{-2/5}(1-\mu^2)^{2/5}(1+\mu^2-k^2\lambda^2)^{4/5} \\ S^{-1/3}(k\lambda)^{2/3}(1-\mu^2)^{2/3}. \end{cases} \quad (26)$$

For a fixed angle of obliquity, the most unstable wavenumber occurs at the intersection of the two regimes, which is $k\lambda \simeq S^{-1/4}(1-\mu^2)^{-1/4}(1+\mu^2)^{3/4}$. Constant- ψ corresponds to $k\lambda$ larger than this value, and nonconstant- ψ to $k\lambda$ smaller than this value. The leading constant coefficients in Eq. (26) are $[\Gamma(1/4)/(\pi\Gamma(3/4))]^{4/5} \simeq 0.95$ for the constant- ψ regime, and unity for the nonconstant- ψ regime. Equation (26) reduces to the classical tearing mode dispersion relation of Eq. (1) for normal modes ($\mu = 0$). The maximum growth rate is $\gamma_{\max}\tau_A \simeq S^{-1/2}(1-\mu^4)^{1/2}$.

Oblique modes ($\mu \neq 0$) are the most unstable in the constant- ψ regime, where the maximum growth rate has angle $\tan\theta = \pm(B_{p0}/B_{z0})\sqrt{(1+k^2\lambda^2)}/3$. Here, parallel modes are a local minimum in the growth rate. This behavior should be contrasted with that in the nonconstant- ψ regime, where parallel modes ($\mu = 0$) are the most unstable, and the growth rate falls off monotonically for oblique angles. In both regimes, $\mu < 1$ is required for instability, otherwise there is no resonant surface.

The plasmoid growth rate can be calculated from the tearing mode dispersion relation by taking the equilibrium to be a Sweet-Parker current sheet, which has width $\lambda = \delta_{\text{SP}} = LS_L^{-1/2}$. With this, $S = (\lambda/L)S_L = S_L^{1/2}$ and $\tau_A = 1/(S_L^{1/2}\Gamma_o)$, where $\Gamma_o = V_A/L$. The plasmoid growth rate in the constant- ψ and nonconstant- ψ regimes can then be written

$$\gamma/\Gamma_o \sim \begin{cases} S_L^{2/5} \kappa^{-2/5} (1 - \mu^2)^{2/5} (1 + \mu^2 - \kappa^2/S_L)^{4/5} \\ \kappa^{2/3} (1 - \mu^2)^{2/3}, \end{cases} \quad (27)$$

in which $\kappa \equiv kL$.

The most unstable angle in the constant- ψ regime is $\theta \simeq \pm (B_{po}/B_{zo}) \sqrt{(1 + \kappa^2/S_L)/3}$ in these variables. The two regimes meet at

$$\kappa_{\max} \simeq S_L^{3/8} (1 - \mu^2)^{-1/4} (1 + \mu^2)^{3/4}, \quad (28)$$

where the maximum growth rate is

$$\gamma_{\max}/\Gamma_o \simeq S_L^{1/4} (1 - \mu^4)^{1/2}. \quad (29)$$

Equation (28) provides an estimate for the number of plasmoids expected to initially arise in an unstable current sheet: $N \simeq \kappa_{\max}/(2\pi)$. Parallel modes generate the fewest number of plasmoids, and the plasmoid number increases monotonically with θ . Equations (28) and (29) reduce to the results of Loureiro *et al.*¹ for parallel modes. Equation (27) also provides the instability criterion,

$$\kappa < S_L^{1/2} (1 + \mu^2)^{1/2}, \quad (30)$$

for the wavenumber.

Figures 4 and 5 show the plasmoid growth rate calculated from the boundary layer theory of Eqs. (12) and (23), as well as from a direct numerical solution of the linear reduced MHD equations (7) and (8). All figures use $B_{po}/B_{zo} = 0.1$. Figure 4(a) shows excellent agreement between the theory and the numerical results for parallel modes at three values of S_L . The $\kappa^{2/3}$ scaling of the non-constant- ψ regime and $\kappa^{-2/5}$ scaling of the small κ limit ($\kappa^2/S_L \ll 1$) of the constant- ψ regime are also confirmed. The solid lines in Fig. 4(a) are obtained using the small $k\lambda$ limit of Eq. (12) [$\Delta'\lambda = 2/(k\lambda)$], which extends the $\kappa^{-2/5}$ scaling beyond its region of validity. This is the limit assumed in Ref. 1 and is shown for comparison. Although the growth rate falls off rapidly for $\kappa > \kappa_{\max}$, the $\kappa^{-2/5}$ scaling holds near the intersection with the nonconstant- ψ regime. The maximum growth rate obtained from the intersection of the nonconstant- ψ regime, and the small κ limit of the constant- ψ regime provides a good approximation of the full analytic, and numerical, results.

Figure 4(b) shows results for fixed $S_L = 10^8$, and different values of the angle of obliquity. Here, too, the growth rate calculated with boundary layer theory compares well with the numerical results. The agreement becomes less favorable for angles very close to the cutoff angle $|\theta_{\max}| \simeq B_{po}/B_{zo} = 0.1$. Figure 4(b) shows that parallel modes are the most unstable in the nonconstant- ψ regime. The constant- ψ regime is found at $\kappa \simeq 10^4$, where oblique modes have larger growth rates than parallel modes. The maximum wavenumber for instability from Eq. (30) shows excellent agreement for all Lundquist numbers and angles shown in Fig. 4.

Figure 5 again shows close agreement between boundary layer theory and numerically calculated growth rates. Figure 5(a) shows the angular dependence of the growth rate

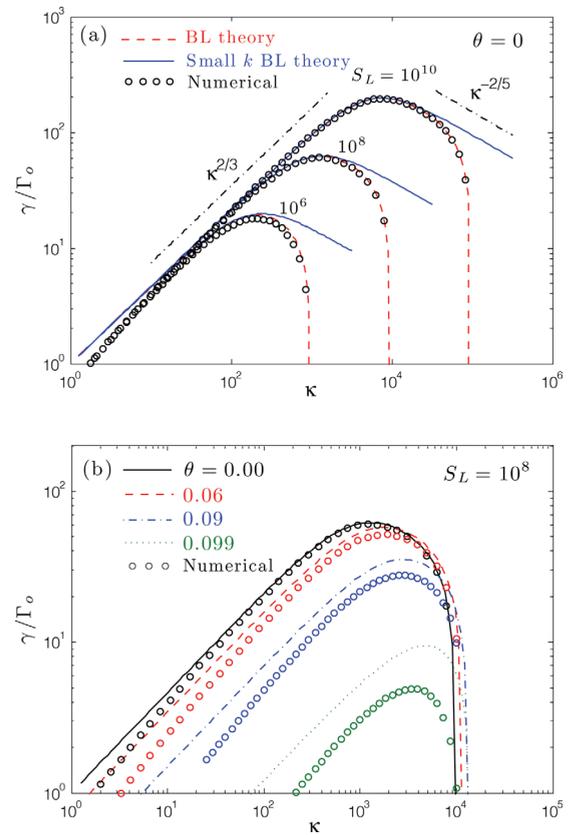

FIG. 4. (Color online) Wavenumber dependence of the plasmoid growth rate for a Harris equilibrium and $B_{po}/B_{zo} = 0.1$. (a) Normal modes ($\theta = 0$) for three values of the Lundquist number: $S_L = 10^6$, 10^8 , and 10^{10} . Circles show the growth rate from a direct numerical solution of Eqs. (7) and (8), red dashed lines from the boundary layer theory of Eqs. (12) and (23), and the blue solid line from boundary layer theory using the small k limit of Eq. (12) [$\Delta'\lambda \simeq 2/(k\lambda)$] and Eq. (23). (b) Oblique modes with angles $\theta = 0.00, 0.06, 0.09$, and 0.099 at fixed $S_L = 10^8$. Lines represent the boundary layer theory and circles the numerical solutions.

for fixed Lundquist number, $S_L = 10^8$, and four values of the wavenumber, whereas Fig. 5(b) fixes the wavenumber and varies the Lundquist number. In both cases, a transition between the two regimes is evident. At small κ , or large S_L , parallel modes are most unstable. Here, the growth rate decreases monotonically with $|\theta|$ until the stability threshold at $|\theta| \simeq B_{po}/B_{zo} = 0.1$ is reached, which is indicative of the nonconstant- ψ regime. Modes at larger κ , or smaller S_L , are most unstable at oblique angles. Here, the most unstable angle agrees with the prediction of the constant- ψ regime: $\theta \simeq \pm (B_{po}/B_{zo}) \sqrt{(1 + \kappa^2/S_L)/3}$.

A contour plot of the growth rate is shown in Fig. 6 for a range of wavenumbers near the peak growth rate and the entire domain of unstable angles. Here, the Lundquist number is fixed at $S_L = 10^8$, and the growth rate was calculated from the boundary layer theory using Eqs. (12) and (23). Again, the angular dependence of modes in the constant- ψ regime is evident. Here, a linear scale has been used for κ , which allows better resolution of the constant- ψ regime. The dashed line shows the estimated κ at the maximum growth rate from Eq. (28), which corresponds to the boundary between the constant- ψ (above the dashed line) and nonconstant- ψ (below the dashed line) regimes.

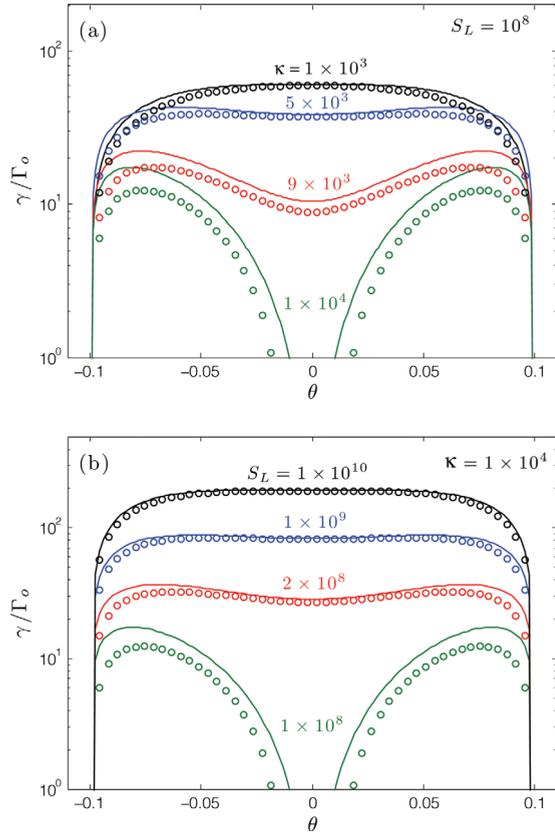

FIG. 5. (Color online) Angular dependence of the plasmoid growth rate for a Harris equilibrium and $B_{p0}/B_{z0} = 0.1$. Lines represent solutions from the boundary layer theory of Eqs. (12) and (23), and circles from direct numerical solutions of Eqs. (7) and (8). (a) For fixed Lundquist number $S_L = 10^8$, and four values of the wavenumber: $\kappa = 1 \times 10^3, 5 \times 10^3, 9 \times 10^3$, and 1×10^4 . (b) For fixed wavenumber $\kappa = 1 \times 10^4$ and four values of the Lundquist number $S_L = 1 \times 10^8, 2 \times 10^8, 1 \times 10^9$, and 1×10^{10} .

Oblique modes in the constant- ψ regime of Eq. (26) are analogous to $n \geq 1$ tearing modes in a tokamak. In fact, all tearing modes in tokamaks are oblique since the presence of $n = 0$ modes would require an infinite safety factor (unless $m = 0$). Furth *et al.*, considered $n = 1$, constant- ψ tearing modes in a periodic cylinder.²⁴ In cylindrical geometry, the linearization becomes $f_1(x) \exp[i(k_y y + k_z z)] \rightarrow f_1(r) \exp[i(kz + m\vartheta)]$, where ϑ is the poloidal direction and $k = n/R$ is

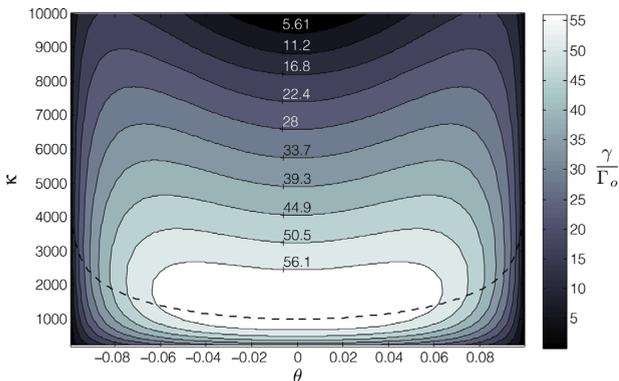

FIG. 6. (Color online) Contours of the plasmoid growth rate calculated from Eqs. (12) and (23) as a function of wavenumber and angle of obliquity. Here, $S_L = 10^8$ and $B_{p0}/B_{z0} = 0.1$. The dashed line shows the estimated boundary between the constant- ψ and nonconstant- ψ regimes from Eq. (28).

quantized according to the tokamak major radius R . In this case, the angle of obliquity is $\tan \theta = k_z/k_y \rightarrow r_s n/(Rm)$, where r_s is the minor radial location of the resonant surface. In terms of the safety factor, $q = |rB_z/(RB_\vartheta)|$, $q(r_s) = m/n$, and

$$\tan \theta = \frac{r_s/R}{q(r_s)}. \quad (31)$$

The angles of obliquity are small for large aspect ratio tokamaks and increase with the ratio n/m simply due to geometry; flux tubes with higher n numbers, or lower m numbers, must travel farther poloidally in a toroidal transit. The existence of a resonant surface and the resulting growth rate both depend on the current profile, which is significantly different in tokamaks than the Harris equilibrium we have assumed above. The effect of periodic boundary conditions on the above analysis would simply require quantization of k_y and k_z according to the length of the current sheet L and the domain size in the guide field direction. In this case, $\kappa \simeq 2\pi m$, and Fig. 4 shows that there are typically thousands of islands in a chain for the current sheet lengths of interest.

V. NUMERICAL EIGENMODE SOLUTIONS

Figure 7 shows numerical solutions of the perturbed flux and stream functions for fixed $S_L = 1 \times 10^8$, $\kappa = 1 \times 10^3$, and four angles of obliquity: $\theta = 0, 0.025, 0.05$, and 0.09 . As the angle of obliquity increases, two significant changes occur: the eigenfunction center shifts, and symmetries of the eigenfunctions are lost. The shift in eigenfunction center corresponds to the shift of the resonant surface: $x_s/\lambda = -\text{arctanh}(\mu) \simeq -\text{arctanh}(\theta B_{z0}/B_{p0})$. For the plotted angles, $\theta = 0.00, 0.025, 0.05$, and 0.09 , the predicted resonant surface locations are $x_s/\lambda = 0, -0.025, -0.055$, and -1.47 , respectively. The gradient of the perturbed stream function in Fig. 7(a) decreases for $x > x_s$, but grows for $x < x_s$, as the angle of obliquity increases. Likewise, the gradient of the perturbed flux function in Fig. 7(b) decreases for $x > x_s$, but remains nearly constant on the $x < x_s$ side.

Figure 8 shows constant flux surfaces, which generate flux ropes in 3D, for a parallel mode ($\theta = 0$ in the top row) and an oblique mode ($\theta = 0.06$ radians in the bottom row). Here, the parameters $\kappa = 10^3$ and $S_L = 10^8$ have been chosen. Also shown in the right column are 2D cuts of the same data, at $z = 0$, showing magnetic islands. The total flux function is used, which is the sum of the equilibrium component, and the perturbed component multiplied by a constant amplitude: $\psi = \psi_o + a\psi_1$. For the values in Fig. 8, ψ is normalized to $B_{p0}\lambda$ and a is chosen to be 0.01. The equilibrium component, ψ_o , is obtained from the definition $\mathbf{B}_o = \nabla_\perp \psi_o \times \hat{z} + B_{z0} \hat{z}$. This implies $d\psi_o/dx = -B_{p0} \tanh(x/\lambda)$ for the Harris sheet, so

$$\psi_o = -B_{p0}\lambda \ln[\cosh(x/\lambda)] \quad (32)$$

is used for ψ_o .

The flux ropes shown in Fig. 8 correspond with the qualitative expectation from Fig. 1. For parallel modes, they are straight and uniform in the \hat{z} direction, which is consistent with taking z to be an ignorable direction in the conventional

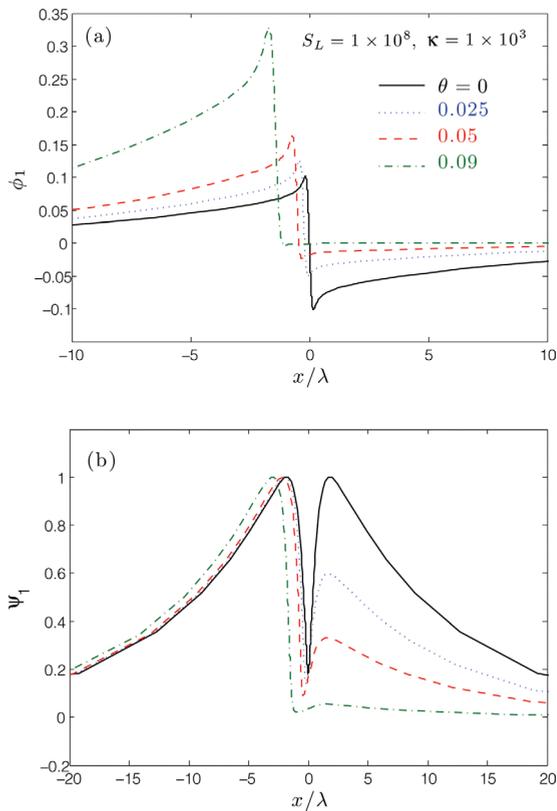

FIG. 7. (Color online) Perturbed stream function ϕ_1 (a) and flux function ψ_1 (b) for $S_L = 1 \times 10^8$, $\kappa = 1 \times 10^3$, and four values of the angle of obliquity: $\theta = 0, 0.025, 0.05$, and 0.09 radians. These eigenfunctions were obtained from a direct numerical solution of Eqs. (7) and (8).

theory. Here, the 2D cuts of magnetic islands are symmetric in x about the resonant surface $x = x_s = 0$. For oblique modes, the flux tubes are shifted by angle θ from the normal in the z direction. Here, the 2D cuts of magnetic islands do not possess the x symmetry of parallel modes, having a slightly shallower gradient for $x > x_s$ than for $x < x_s$. The resonant surface is also shifted slightly $x_s/\lambda \simeq -0.055$.

VI. SUMMARY

Oblique plasmoid instabilities were analyzed within the context of the reduced MHD approximation. This required accounting for the 3D effect of wave variations in the guide field direction, which is the ignorable direction in the 2D theory. An important difference between the 2D and 3D theories is the location of the resonant surfaces (where $F = \mathbf{k} \cdot \mathbf{B}_o = 0$). Considering a Harris equilibrium with guide field, this can take any value in 3D: $x_s = -\lambda \arctanh[k_z B_{z0}/(k_y B_{p0})]$. In the 2D case, $k_z = 0$ and the resonant surface is always the null surface of the poloidal equilibrium field. The same is true in the 3D case only if there is no guide field present. The boundary layer analysis changed primarily in the outer region, where Δ' depends on the angle of obliquity [see Eq. (11)]. The approximate Δ' expression we obtained for a Harris equilibrium was shown to compare favorably with a numerical solution of the ideal MHD force balance. In the inner region, the angle of obliquity only entered in locating the resonant surface when evaluating $F'(x_s)$.

We found that unstable modes are confined to small angles $|\theta| < \arctan(B_{p0}/B_{z0})$. In the constant- ψ regime, the most unstable tearing mode is an oblique mode

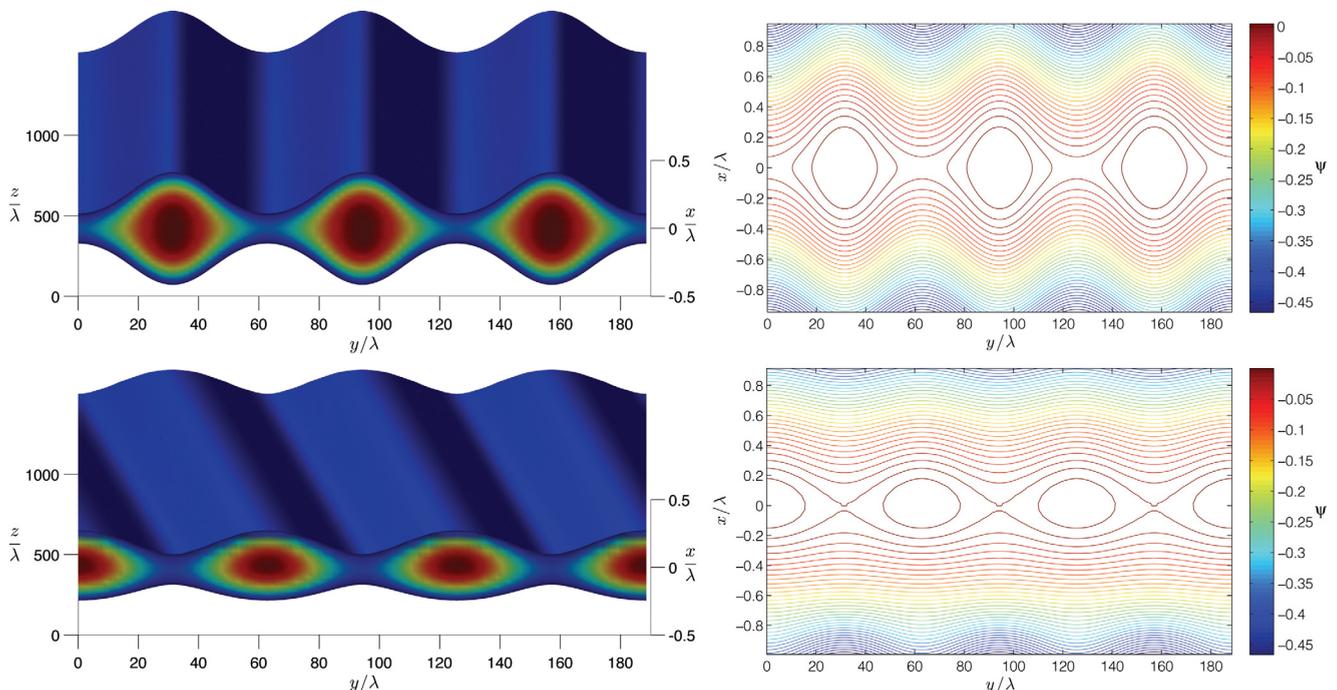

FIG. 8. (Color online) Three-dimensional flux ropes obtained from isosurfaces of the flux function, along with corresponding magnetic islands obtained from 2D cuts in the $x - y$ plane. The \hat{x} direction is vertical and \hat{z} direction mostly into the page in the figure. Here, $\kappa = 10^3$, $S_L = 10^8$, and $B_{p0}/B_{z0} = 0.1$. The top row is a parallel mode, where $\theta = 0$, and the bottom row is an oblique mode, where $\theta = 0.06$ radians. The colorbar corresponds to colors in the 2D plots and represents values of constant flux normalized by $B_{p0}\lambda$.

$|\theta| \simeq (B_{p0}/B_{z0})\sqrt{(1+k^2\lambda^2)}/3 \neq 0$. In the nonconstant- ψ regime, the most unstable tearing mode is a parallel mode ($\theta = 0$). The most unstable wavenumber is located at the intersection of these two regimes. The growth rate for this wavenumber is largest in the parallel direction. By choosing an appropriate wavenumber at fixed Lundquist number (or vice versa), it was shown that a situation can arise in which only oblique modes are unstable. The boundary layer theory was shown to compare well with numerical solutions of the linear reduced MHD equations.
